Chapter 1

Why I Care - Network Earth

1.1 The Biosphere

Take a breath.

Washing into your lungs is a rich mixture of gasses containing the all important and life giving element - oxygen. While you may traditionally think of oxygen as coming from the plants around you, it turns out that the mixture swirling about in your lungs comes from a much wider and more exotic set of sources. The majority of the oxygen you

6 CHAPTER 1. WHY I CARE - NETWORK EARTH

are breathing comes from our oceans - one in five breaths from a cyanobacterium named *Prochlorococcus* [22]. On the complete other end of spectrum are rain-forests like the Amazon - a place that produces something close to one in ten of your breaths [20]. The result of this is that the brew of gasses swirling around in your lungs has come from creatures smaller than the single strands of hair on your head to those as tall as multistory buildings. However, the story doesn't end there.

If you're near some kind of urban center, you probably deal with some level of pollution. The daily goings of urban living produce loads of pollutants such as nitrogen and sulfur dioxide. However, plants have a habit of pulling such pollutants out of the air and storing them safely away in their tissues. In fact a 2006 estimate found that in the United States alone urban forests were responsible for more than 3 billion dollars of air purification [6]. So while most of your oxygen was sourced from our oceans and rainforests, it's purification was local and done by the trees and shrubs in your back yard.

Take a bite.

If you happen to be eating cassava from South East Asia then you can thank a tiny parasitic wasp - *Anagyrs*

lopezi - that is reared in the millions to control populations of a devastating pest - the mealybug [25]. An enormous boon for both the financial and food security in the region, the economic value of this millimeter long wasp is more than \$14 billion a year.

If instead you're dining on a lovely, flaky slab of wild salmon, you are effectively eating the entire ocean. As predators that sit relatively high in the food chain, they depend on "bait fish" like herring as their primary source of food. Herring feed on things like krill, who in turn eat the very plankton providing us with the majority of our oxygen. If any one of these levels in the food chain starts to experience issues so too does your flaky slab of salmon.

Finally, if there are plants on your plate there's a reasonable chance you can thank the leagues of beetles, flies, butterflies, and wasps managing pollination in our world. These services are supplied to an estimated 75% of crop species, and are worth something upwards of \$200 billion every year [35]! Without the insects pollinating the plants that produce our food the variety in our diet would shrink dramatically.

Go on vacation.

8 *CHAPTER 1. WHY I CARE - NETWORK EARTH*

Diving at a coral reef? The colors, the vivacity, the sheer brilliance of all the fish darting this way and that around you? It's thanks to the sharks. Sharks specifically target sick or unhealthy fish, thereby improving the overall health of fish populations and possibly preventing outbreaks of disease [33]. Furthermore, they help prevent the kinds of population explosions that lead to mass die offs. Just another way they preserve the fish we all love seeing.

Hiking alongside giant sequoias or passing through the incredibly diverse south african fynbos? Both of these are only possible thanks to the drama of fire and lightning. Sequoias depend on fires to open their tightly sealed cones and the resultant sprouts depend on the brush clearing power of the fires to give them any chance of seeing the sun [24]. Then, of the more than 9,000 plant species found in South Africa alone, many, like the proteas, also depend on fire to release their seeds and prepare the ground for the next generation of amazing [16]. So why do these fires occur? Lightning is the spark, but the reason the fires spread is thanks to the vast diversity of plants that leave behind dried out remains. When it comes to sequoias and proteas, it truly takes a village.

Enjoying all the ocean has to offer in Florida? Thank

the mangroves. Not only do mangroves provide nurseries for an incredible diversity of creatures including the fish that crowd coral reefs and the manatees and birds that people flock to see (pun intended), but they are also veritable buttresses against coastal damage. One estimate suggested that during Hurricane Irma in 2017 they prevented over a billion dollars of flood damage! That's a lot of insurance.

Take a step back.

These examples are just a tiny taste of how *every single aspect of our lives* is deeply, intrinsically dependent on the living world around us - the biosphere. The Millenium Ecosystem Assessment identified 25 different categories of ecosystem services - and these are as broad as things like food provisioning and erosion control [2]! From millimeter wasps to three hundred foot tall trees, from ecosystems half a world away to the shrubs in your back yard, our world provides our food, water, air, health, happiness, and so much more. It is our life support system, our spaceship as we hurtle through the vast, cold emptiness that is space and for the first time in our history we have the power to overwhelm it.

1.2 The Anthropocene

Let's start with some perspective. We as human beings have a very hard time thinking about pretty much any period of time longer than the ones we've already lived. Tell me something is ten years old - no problem I can grasp that. Tell me something is one thousand years old? While I can make it out mathematically I really don't have any way to grasp just how much longer that is. 100,000 years? Forget about it. So let's use a frame of reference that's a little easier to understand. Let's pretend all of our universe's history fits in a single year [30].

From this point of view (and if we accept standard scientific time lines) the big bang starts us off at midnight January 1. The next four months are spent in a dizzying dance of expanding hot gas, newly forming stars, and, finally, galaxy formation with the milky way only showing up around May [9]. But don't assume that because of this our time line is about to speed up because we still have to wait until September before our solar system even forms! We've gotten roughly three quarters through our year and our planet has only *just* shown up. Surprisingly, given how long it's taken to get to this point, it only takes 20 days for the first things we'd deem living to show up, but then things slow down again as we have to wait until December (around 70 more days) before the first multi-cellular

organism joins the scene. Now things really start to take off.

15 days later we've got plants colonizing the land masses of our planet. 3 days after that the first reptiles join them. Only a mere two days later and we've entered the age of the dinosaurs. Think about that, in less than a third of the time it took to figure out how to make multi-cellular organisms we've gone from nothing macroscopic on land to dinosaurs! A day later, our ancestors - the first mammals - join the production and by December 30th (4 days later) the first primates appear.

But hold on one second. Did I just say December 30th? Does that mean we've got 1 day left in our year and humans haven't even shown up?! That's right. But it gets even wilder. *Homo sapiens*, us, don't show up until 12 *minutes* to midnight. Just chew on that for a second. All of human history, finding fire, inventing tools, starting the first cities, all the empires, all the wars, absolutely *everything* that our species has ever done occurred in the last 12 minutes of our universe's year. That's the amount of time it takes to heat up a microwave dinner!

But it gets even wilder because we, as a species, didn't figure out how to farm until 28 *seconds* before midnight. So really, everything you've learned about in your human history courses gets packed into about as much time as you spend watching a *single* tiktok. We are but a blip in

12 CHAPTER 1. WHY I CARE - NETWORK EARTH

the history of our universe. But, oh, what a blip we are.

From nature's perspective, humans have generally been, with few exceptions, a footnote. There's a reason why the oceans were terrifying to early humans, or why people prayed to gods to stave off floods or famine. If nature decided to have its way, there was little we could do about it. But post the industrial revolution and especially since 1950, that relationship has *utterly* changed [9].

Let's start with some simple numbers. Around 71% of the land on our planet is considered habitable [28]. Of that habitable land we have put around 46% of it into agricultural production. That means we use a solid *third* of the planet's surface (not covered by ocean) to just feed ourselves. Except that we eat more than what's on the land. When it comes to fishing the picture is even wilder. Of global fish stocks we overfish 34% percent and maximally fish 60% [29]. That means there are only 6% of fish stocks that we could fish more without starting to deplete their numbers!

The amount of water we use is no less incredible than the amount of area we farm. Each year approximately 40,000 km^3 of freshwater flows into the ocean [9]. Of this only around 13,000 km^3 is accessible to humans with our current technology. Yet nearly half of that flows through human engineered systems! So not only are we using half

of the accessible land, and pretty much all of the accessible fish, we're using half the available fresh water too.

In the 2004 the International Geosphere-Biosphere Programme published a report that illustrated what is now called the Great Acceleration [13]. Across 24 distinct measures from total GDP to atmospheric carbon to the number of rivers dammed they found an explosive spike in activity starting in the 1950's. We've already talked about a few of them (farm, fish, and water use) but let's sprinkle a few more in for color.

Since around the beginning of the 1900's we've lost 30% of our forests. We've now dammed close to 25 thousand rivers. We consume about 300 million tons of fertilizer per year. Our global population has gone from 2 to 7 billion. And we have more than 3 times as many floods as we used to per decade. But here's the one that kind of summarizes it all for me - extinction rates have gone through the roof.

Extinctions are nothing new and in general pretty normal. As time marches on species come and go and that's... well... just evolution doing its thing. So what matters is not *whether* extinctions are happening but *how many* are happening.

In the past we've had some pretty spectacular extinction events. Around 444 million years ago the Ordovician-Silurian extinction took out around 70% of everything liv-

14 CHAPTER 1. WHY I CARE - NETWORK EARTH

ing at the time [7]. 372 million years ago the Late Devonian extinction took out some 70% of all marine species. The Permian-Triassic extinction, which occurred roughly 252 million years ago, took out over 70% of everything alive again. Then in the Late Triassic (208 million years ago) we had yet another mass extinction. Finally we have the most famous of them all, the Cretaceous-Paleogene extinction where 66 million years ago over 60% of all species died as the result of a massive asteroid smashing into our planet and creating the equivalent of nuclear fallout. Bad for the dinosaurs but great for us as mammals often are attributed their place center stage thanks to that big old space rock.

Since we were visited by Armageddon-a-la-space extinction rates have pretty much held at their normal, background levels. Until, that is, the Great Acceleration. Since the 1950's extinction rates have skyrocketed to more than 1000 times their background rate [14]! At the current rate scientists estimate that 50% of all species could be gone by 2100. We have entered the sixth extinction.

Here is where our current impact on our biosphere really comes into perspective. Mass extinctions in the past have occurred as the result of insanely powerful events. Country sized asteroids smashing into the planet. Massive anomalies in global temperatures (sound familiar?). Such incredible dips in the amount of oxygen that more than

70% of all living species just... well... died of oxygen deprivation. Causing mass extinctions requires planet shaping power. *We now possess that kind of power.* And as a result we've entered an entirely new geological epoch, an epoch where humankind is the domineering, world shaping, power - the Anthropocene [9]. And in the perspective of our "universe in a year" we managed this power grab in less time than it takes to watch a tiktok.

Contrary to how you may be feeling, none of this is meant to scare you (although fear and awe are perfectly appropriate reactions). Instead it's meant to impress upon you the gravity of our situation. In the first section we got a glimpse of just how important the biosphere is to us and now you've got a taste of just how powerful we, as a species, have become - that asteroid that took out the dinosaurs is taking notes from us now. Thankfully this power means that in so much as we can absolutely wreck our world, we can also take care of it too. The problem is not that our world is doomed, but rather that we can no longer just take it for granted. Given our planet shaping capabilities we have no choice but to become active, conscious stewards of our planet. So the question is simple, how do we do that?

1.3 A Revolution

Suppose for a moment you have a garden. While at first it may seem like all you need to do is water your plants and let them flourish, anyone who's tried gardening before knows there's a lot more to it than that. For one thing watering is a tricky business. Water too much and your plants can get water logged and die. Water too little and your plants will wither up and die. Plant your plants too close together and they won't be able to grow properly. Plant them too far apart and you'll be wasting loads of garden space. Then there are the pests. Caterpillars, beetles, mice, deer, you name it it's probably trying to eat your plants and every single one of these needs a different strategy for dealing with. Then there's disease. Plants, like us, can get sick and it's especially likely if they're not getting the right balance of nutrients and care. Diagnosing these sicknesses is difficult enough that there are apps to help you with the task and then there are a whole slew of different methodologies to deal with the various ailments. And we haven't even gotten to the fact that choosing plants can be its own nightmare. Do you have enough sun? Too much sun? Direct or indirect? What's the soil quality, what's your growing zone? On and on it goes. Point is, stewardship of your garden requires a lot of specific knowledge about the plants you a growing, their

life histories, the life histories of everything they interact with, the place you live in, and so on.

So now replace your garden with the entire world. Obviously the amount of knowledge you need is going to skyrocket but something else changes as well. In your garden you've got lots of room to learn by trial and error - if you manage to kill a plant (like I tend to do) it's no big deal, just try again next year or in a different plot in your garden. We, however, have only one world. While we can certainly try little things here and there, at the end of the day, we've got to be pretty sure we know what we're doing before we launch large scale efforts to shape our world one way or another. And that requires models sophisticated enough to let us trial things in simulation. So not only do we need a lot of knowledge about how our biosphere works, we also need to make sure it's the kind of knowledge that allow us to build simulations. Turns out, this kind of science is pretty new.

Some history. The scientific revolution started in the 1500's and was set off by Copernicus' now famous idea that perhaps we aren't at the center of the universe [4]. What followed was a massive explosion in all things astronomy and over the course of a few hundred years everything we thought we knew about our place in the universe changed. In 1620 Robert Hooke discovered cells for the

18 *CHAPTER 1. WHY I CARE - NETWORK EARTH*

first time launching the whole field of microbiology [37]. In 1735 Carl Linnaeus put together the system for classifying plants and animals that we use to this day and in 1745 Ewald Jürgen Georg von Kleist invented the first capacitor. Fast forwarding to the 1900's and we've got Max Planck's theory of black body radiation in 1900 followed quickly by Einstein's special relatively and his explanation of the photoelectric effect in 1915 - all theories that were seminal in the creation of modern physics. In 1953 Wilkins, Franklin, Watson, and Crick made the now famous discovery that DNA has a helical structure - thereby totally changing our understanding of the stuff - and in 1996 we cloned a sheep for the first time. So, given all of this progress, you might be surprised to learn that it was only in 1999 that Hans Schellnhuber published a "ground-breaking" paper on earth system modeling that spoke of a "second Copernican revolution" in our ability to model the biosphere [31]. Our first thoughts on this issue came around the same time as our ability to clone things and well after we came up with the idea of black holes in space.

To understand this we need to look at what was going on alongside each of these revolutions in science. The scientific revolution, with all of its progress in astronomy, came at the same time as the first telescopes were being invented. Hooke made his discoveries about the cell thanks to the newly invented compound microscope. Lin-

naeus only came up with his system of taxonomy after extensively traveling the world - something only possible thanks to all the nautical inventions that also created the "age of discovery". The first electrical inventions were all thanks to developments in what materials were becoming available as the industrial revolution unfolded [19]. The discoveries of modern physics were all thanks to continuous improvements in our ability to poke at smaller and smaller things using tools like the x-ray diffraction techniques that allowed Wilkins, Franklin, Watson, and Crick to infer the structure of DNA. The pattern from all of these examples should be pretty clear - to understand our world we need the tools to probe it and each scientific revolution has been attended by updated capabilities in our ability to gather data [19]. So it should come as no surprise then that one of the major tools used by earth system modelers - satellites - are a relatively recent development. As an example, the Landsat program, one of the largest programs to provide satellite imagery of Earth, only started in 1972 [36].

But satellites are only part of the picture and the need for further instrumentation and tooling is clear. Whether it's land management [12], pollination services [3], or general biodiversity management [11] (just to name a few) scientists in recent years continue to point to a lack of comprehensive data as one of the primary challenges they

face world over. Science is driven by data, and the data is sorely lacking.

So if we want to spark another scientific revolution, one that will give us the tools we need to be good stewards of our planet, we need to start providing the instrumentation required. So question is - how do we do it?

1.4 An Aside

Before we dive into how to develop instrumentation I want to stress something. The last section argues that we *need* models of our biosphere and all the attendant knowledge in order to be good stewards of our planet. I firmly believe this is true. However (and this is important) I *do not* believe that such knowledge should block actions that are already supported by the science that exists *today*. I *do not* believe we should wait to decarbonize or wait to stop wasting as much as we do or wait to stop polluting. These are all good, clear actions that should be taken *now* because the science clearly backs them. In general there will always be gaps in our knowledge that need filling, so if we ever want to be good stewards who actually take action we have to learn to listen to the knowledge we have.

Alright, back to the scheduled programming.

1.5 An Industry

We've got a problem. While pointing out the immediate need for biosphere instrumentation is cool and all, it's also laughably vague. How on earth are we supposed to execute on a mission statement that's that high level? Fact is, we need a strategy.

Strategies start with understanding our goals and, especially in our case, clarifying goals is really important. The history of conservation and "biosphere activism" has... well... a checkered past. Early biologists exploring the pacific islands sometimes caused extinctions in "the name of science" and part of the reason we're having to reintroduce wolves all over the place is that early conservationists helped get rid of them in the name of creating a more bounteous United States [23]. At the other extreme, in my own experience, I've found that frustration with human negligence often leads to a desire to take humans out of the picture entirely, a philosophy that culminated in the Half-Earth Hypothesis - a proposal that we should set aside half of the planet as a human free zone (and they're not talking about totally uninhabitable places) [38].

But let's look at intentions. The folks causing extinctions in the pacific islands? They just wanted to study birds. Unfortunately, at the time, studying birds was synonymous with shooting them. So while studying birds is

22 CHAPTER 1. WHY I CARE - NETWORK EARTH

a great idea, shooting them all as a means to an end is a little more than short sighted.

How about the wolves? Well quite a lot of the money in conservation coffers comes from hunters. So making our forests more bounteous isn't a half bad idea. The problems are twofold. First, it turns out wolves are needed to keep deer populations healthy (ecology!). Second, extirpation is a really extreme take on "reducing" wolf populations. So once again, reasonable intentions with a short sighted strategy.

Finally I get the frustration with people seemingly just bulldozing everything that isn't "producing human good" or treating the natural world with less than respect. But the problem here is one of education - rather than understanding that rainforests are useful natural resources, most economies see them as unrealized cattle farms instead. The problem isn't that humans are included, it's that those same humans aren't including the natural world in their calculus.

Regardless of the various strategies taken, one thing is clear from all of these examples. The goal is to nurture the value that our biosphere provides us. Unfortunately this is still too vague for our purposes so let's dig deeper.

The Millennium Ecosystem Assessment [1] suggests a rather lovely framework for thinking about all of this.

They suggest (and the suggestion is backed by data) that human well being exists on a continuous spectrum with poverty that is made up of five key components - the necessary material for a good life, health, good social relations, security, and freedom and choice. So while you may have a lot of material wealth (1) if your health (2) is extremely poor because of, say, pollution, you are still impoverished to some degree. In other words there is no such thing as poor or wealthy. Instead there is a five dimensional spectrum that we have to keep our eyes on at all times.

As a quick example of why this is important, almost every assessment of ecosystems that I have read is stated in dollars. Even the first section of this essay had a dollar bent! But how do you put dollar values on social relations, feelings of security, or autonomy? You obviously can't! Having these five dimensions of human well-being helps us break out of the habit of only seeing value as economic. And this level of specificity and holism is exactly what we need in our goals.

Okay so that gives us a better sense of how to make sure we're measuring value completely, but how on earth are we supposed to connect this back to the literal jungle's worth of complexity in our biosphere? Trying to work out all the ways in which our biosphere provides for, say, our health brings the phrase - boiling the ocean - to mind. Clearly

24 *CHAPTER 1. WHY I CARE - NETWORK EARTH*

we need to divide the problem up into more manageable parts. Once again, the Millennium Ecosystem Assessment is here to help [2].

As I mentioned before they have already done the work of divvying up ecosystem services into nice neat bins. At the top level we have three overarching categories - provisioning services, regulating services, and cultural services - which are each then divided up into specific sub categories such as food and fiber, water regulation, pollination, sense of place, disease regulation, and so forth. These, obviously, are much more manageable pieces of the overall biosphere pie.

Alright, let's bring this all back. How does this help clarify our path to building biospheric instrumentation? Well first we know now that there are 25 specific models that we are trying to build - one for each ecosystem service category. Second we know that in order to be complete, those models need to be capable of helping us predict the effects on each of the 5 dimensions of human well-being. Finally we know that those models need to be comprehensive. So we can clarify our path forward as such - we need to help scientists obtain the data required to build comprehensive models that connect each of the 25 ecosystem service categories outlined by the Millennium Ecosystem Assessment to the 5 dimensions of human well-being.

Which leaves a much simpler question - what data is required?

Here, we come to the kicker. Scientists have not exactly been twiddling their thumbs. Huge strides have been taken in learning how to think about and model this kind of stuff. Remember, the issue scientists have is not in having *no* data, it's in not having *enough* of it. Pull down the journal Ecological Informatics and you will find *hundreds* of examples of instrumentation techniques that scientists have already developed and proven useful. They've already done the de-risking work and know what data they need - they just need help deploying the instrumentation at scale! And doing this, would be a real value add.

Think about it this way. Most of us could, if we really wanted to, wire our own homes, do our own plumbing, and so forth. But doing so requires buying all sorts of tools, learning all sorts of techniques, going through all sorts of safety training, and so on. That's a lot of overhead for one house. A professional electrician also has to go through all of this overhead but then they apply their tools and training to loads of homes. This is the economy of scale - and it makes a big difference. We absolutely need this same economy of scale if we're going to attempt biosphere-wide instrumentation. And that means we need professional instrumentors. Put a slightly different way, to achieve the

economy of scale, biosphere instrumentation can't just be limited to a research activity - it needs to be its own industry, driven by its own professional workforce. To trigger the scientific revolution we want, we need to build an entire industry.

1.6 Conclusion

If we're going to be sophisticated stewards of our planet, we need a scientific revolution in biosphere modeling. Scientific revolutions in the past were driven by revolutions in instrumentation. Today is no exception. Our strategy? Using the 5 dimensions of human well being and the 25 ecosystem service categories outlined by the Millennium Ecosystem Assessment as a guide, find the researchers already building the instrumentation we need and create professional industries dedicated to deploying and maintaining that instrumentation at scale. Let's create a biosphere instrumentation industry - let's create Network Earth.

Chapter 2

Why This Book?

When I was a child, my family lived across the street from a wonderful little pond. Every time it rained our yard, the road, and, of course, the pond itself would become chock full of amphibians. I'd run out there in the rain and catch several of them to keep for a few a days in the bank of terrariums that my parents had purchased for my brother and I.

My brother and I just liked playing with them. We'd line em up and see which could jump the farthest, we'd build places for them to live with Legos, and before we let them go I'd take pictures of the patterns on their skin so I

could check if we'd met before. Then, after their short stay was over, we'd bring 'em back to where we found them and let them go on their merry way.

I like to think that the stay with us was pleasant for them as much as for me, but I suspect that I got the lion's share of joy out of those interactions. Indeed catching critters was such a formative part of my life. I became obsessed with learning everything I could about the living world and had stacks upon stacks of National Geographic issues, natural history books, and field guides. It seemed obvious to everyone around me that I'd end up becoming a biologist of some kind. However fate had other things in mind.

Through a whole of series of events and existential crises that seem as bizarre to me now as they did when I was a hormonal teenager, at the age of 16 I found myself in a dormitory at Worcester Polytechnic Institute (WPI) to study physics of all things. But physics soon turned into math and by the end I'd given up on that too and was teaching myself software engineering and machine learning. Upon graduating with a math degree (I switched to computers too late) I took up a role as a "Member of the Technical Staff" at a telecommunications company that I'd interned with the prior summer.

Over the next couple years I ended up being relatively successful as an engineer and even ended up co-managing the team I was on for a while (something I was wholly unprepared for). However throughout that period I just felt like there was something missing in my life and so, after another existential crisis or two, I ended up wondering if it was time to return to my roots - wildlife biology and conservation.

Thankfully I did the rational thing and decided to run a small experiment instead of just quitting my job wholesale - over the course of an academic year I took a marine biology course and a class in conservation. In the process of taking these classes I came to the realization that the kinds of technology I had been building over the past few years were almost completely absent from both biology and conservation. It was clear that those in the field could stand to take advantage of what I knew and so (at the advice of my professor) I started looking around for ways to volunteer my skills.

Over the next couple of years I volunteered with a bunch of different groups. At one point I helped a couple biologists automate a machine learning pipeline. At the end of that project it was clear that what we'd just

built could be applied to so many other things, yet that project (for reasons I still wonder about) just sort of disappeared. I ended up working with a marine rehabilitation group and after a couple of months doing a lot of manual, analog stuff that definitely could get automated started floating the idea of modernizing some things. I was very quickly shut down and left a few months later. At another point I started contributing to an open source project that was dear to me but quickly found that they were so overwhelmed they could only really hand off more trivial work to outsiders. Indeed in perusing their forums I quickly discovered that due to a lack of funding they had to shut down most of the more interesting features people using the tools wanted. All of this left a rather sour taste in my mouth. I couldn't get away from this feeling that I had so much to offer but no one seemed to have the time nor resources (and in some cases vision) to take advantage of it. Everyone was happy to take my money, or put my time to menial tasks, but no one really had a place for my *actual* skills.

So, after a time, I decided to take things into my own hands. If others weren't going to put my passion and brain to use I would - and after months of reading, talking to people, writing, prototyping, and thinking I came up with the idea for Network Earth. But as I began working on

that project something clicked in my brain.

The whole idea behind network earth is to create industries around the kinds of technology that can help us instrument our biosphere. There are 25 different ecosystem services to monitor and loads of technologies to manage in each. I suddenly realized that Network Earth didn't just solve my own problem, but it could provide a direction for anyone else in my position - and goodness had I met a lot of those people. When working at the rehabilitation center I'd been surrounded by *actual medical staff* who were being tasked with nothing more than doing laundry and mopping floors. In both of the classes I took nearly everyone there had loads of energy and ideas and each of them was looking for a way to help out. At work itself I was surrounded by colleagues anxious about the state of our world but unsure of how to become involved. So much skill, talent, passion, time, money, and energy with nowhere to go.

And so I had an epiphany that I probably should have had ages ago (but as they say, better late than never) - the real problem to solve here is not the biosphere stewardship crisis but how to harness all the energy and skill of those who *already want to do something about it!* If I could build the organization that I had spent the last few years looking

for I could harness that energy and end up being a much more effective force of change than if I built one specific technology to solve one specific part of the problem.

This, however, presented a problem. While I had some small amount of management experience I was totally unprepared to *build an organization from scratch*! I clearly needed to learn organization development and quickly. Thankfully the stars happened to align in my favor.

Learning anything comes in two parts - theory and practice. Without the theory there's no way for you to "stand on the shoulders of giants" and learn from those who've come before you. But without practice it's all in one ear and out the other. Theory I knew I could do, I'd just simply read everything I could about organizational development and management until I felt confident there wasn't much left that would surprise me. But practice was going to be the harder thing to sort out. Happily, at around the same time as this epiphany I ended up getting something of a promotion at work and found myself co-leading a team of about a dozen people. And that team was tasked with building out a component of our broader organization that, up until that point, never really existed in any clear form. I found myself with a perfect mirror to the problem I wanted to solve - I had a group of brilliant

people who's energy needed to be harnessed toward an organization that did not yet exist. Ample opportunity for practice had just landed in my lap!

Which brings us to why I started writing this book.

This book serves two purposes. First, I'm a firm believer that you don't really understand something until you can explain it to someone else. Therefore I am using the process of writing this book to firm up my own understanding of organization development. However I am also a firm believer in self organizing systems. To my mind the best systems are ones that can build themselves and so, if I do end up being successful in building organizations, part of that success is going to come through teaching others, within the organization, how to build organizations themselves. When that time comes I hope this book will be a central resource.

So, this book is nothing more than the compendium of the things I've learned about organizational development. And while a lot of it is going to feel philosophical or abstract in nature you can rest assured that I myself lean upon these principles each and every day I spend leading teams, building organizations, and dreaming of a better world.

Chapter 3

How This Book is Organized

To me building an organization can be summarized as such - you start with a dream and know you've succeeded when you've made that dream actionable and you're executing toward it. As a result, building an organization is all about resolving the specifics of that dream. Like a sculptor who starts with a block of material, chisels out the general shapes, and then begins working on the details and textures, organizational developers start with broad questions and then work our way down to questions about finer and finer details.

This book then is an attempt to outline, as clearly and methodically as possible what those questions are, when to ask them, how to go about answering them, and what answers look like. However there are two dramatically different ways of presenting these questions that each serves a different, but very important, purpose.

The first is to build your intuition around why these questions exist, for what purpose, and why they take the form they do. This treatment is given in the first part of this book - **Intuition**. The second part of the book is far more practical. Theory is great and all but it can be hard to translate it directly into action to take. Instead, when it comes to actually putting things into practice, a manual is a far more useful tool. So the second part of this book - **Action** - attempts to play that role. As such it's not really meant to be read in linear sequence like a normal book, but instead to act as a practical reference for obtaining specific protocols to follow as you go about resolving your organization. However, without the theory it'll be terribly difficult to use the second section - hard to use a car manual to repair a car if you have no clue how a car works.

So, when you're using this book, consider taking the following approach. Read through the **Intuition** entirely

to ensure that you've got your bases covered and then, like you would for mending a car, use **Action** opportunistically, taking what you need, when you need it, and nothing more.

Happy reading!

Part I

Intuition

Chapter 4

Creating Catalysts

4.1 Skill

It's a reasonably well established fact that the average human being can only hold around 7 things in short term memory at once. Put another way, if I start sounding off digits to you in quick succession you'll only reliably be able to remember 7 of them at a time. However there are a rare handful of people out there who blow this number straight out of the water. There have been people who've been able to recite upward of 80 digits consistently and others who've been able to demonstrate this trick for 100's of digits at a time! Given the rather measly limitations on the

average human's brain you may be wondering what makes them so special. The answer? Nothing at all.

For example take Steve Faloan - a student the psychologist Anders Ericsson recruited to study how far people can push their short term memory. When Steve first started he, like the rest of us, could only reliably recite 7 or 8 digits from memory. Yet by the end of this experiment he was reliably reciting 82 digits at a time! How had he made this jump? By using mnemonics. Being a runner, Steve realized that he could group series of numbers into running times. So if he saw the digits 1, 0, 3, 5 he'd remember the running time 10 minutes and 35 seconds. This alone allowed him to focus on remembering 7 running times instead of 7 digits which translates into around 28 digits overall. A huge leap forward! By continuing to create structures like these that made better use of his normal short term memory, he was effectively able to extend his short term memory by over 10 times.

Another feat of intellect that seems near miraculous to the rest of us is the ability of master chess players to play blindfolded or without a board. Indeed many master chess players have taken this to the extreme with some playing a couple dozen games simultaneously all while unable to see or touch any of the boards! Wondering what sets them

apart, a set of psychologists performed a rather interesting experiment. They took a national-level, mid-level, and novice chess player and showed them a board with a whole load of chess pieces arranged in a way that might arise from a game of chess. Then with the board removed they asked them to recall the arrangement of the pieces. Unsurprisingly, the better the person was at chess the better they did at remembering the pieces and where they were. But then they showed those same people a chess board with *randomly* arranged pieces, took the board away, and asked them to recall again. Surprisingly in this case there was no longer any difference in performance! The national-level chess player no longer had any advantage.

In interviews with a variety of experienced chess players, it has become clear that what they are seeing in their head when they play chess with no board are "chunks" of interacting pieces. They'll see setups that they are familiar with from prior games, lines of attack or pressure that have been important in the past, etc. And so when you randomly arrange the pieces on the board, none of these chunks can be found and so the ability to remember it with any level of real skill goes away - once again the exceptionalism is coming from specific mental representations that they've built up.

Ericsson and others studying exceptionalism have found this pattern over and over again pretty much everywhere they've looked. From swimmers being taught ways of perceiving their body and performance as they swim to musicians learning music theory to physicists learning the math they'll need to represent the universe - mental representations seem to be the key to gaining these incredible levels of skill. As Steve was finding ways to better take advantage of his limited short term memory so too are masters in all of these areas finding solutions that allow them to break through to the next level of extraordinary.

However, all of this should be setting alarm bells off in your head. If it's just a matter of learning mental representations, why on earth aren't we all master chess players and elite swimmers? Clearly we're missing something. To see what it is consider the pipe organ.

Playing the pipe organ (the kind you find in an old church) is no easy feat. There are usually multiple keyboards which you'll end up playing separately with each of your hands, a pedal board for playing notes with your feet, dozens of stops that control what *kind* of sound each keyboard produces, volume levers, and then of course there's the matter of actually playing itself - reading music, coordinating your fingers, keeping tempo, knowing how to

interpret the music, and so on. Clearly if you try to actively *think* about all of these things all at once you'll get overwhelmed. Instead you've got to make each of these components instinctive so that you can use your conscious mind to work on coordinating it all rather than trying to work out all the little details in real time. In other words you've got to work the underlying skills into your intuition.

Everyone who's practiced something knows that when you first start, whatever you're doing is *hard*. However if you keep up consistent and regular practice over time, what was hard ends up becoming relatively easy. Why is that? Well it has to do with the notion of homeostasis. All your body wants is for normal life to be... well... easy. So when it suddenly finds that every day you, for some unfathomable reason, find yourself running, it figures out that if this is gonna keep up it had better reconfigure things in order to make the run less of a pain. So it starts building blood vessels and musculature to turn your daily run into just another part of the norm. It shifts your statis state - your homeostasis.

Turns out the same thing happens for these mental representations we've been talking about. When you first start using them, your brain is rather clunky about it. Like the first time you did algebra or started reading you have

to think really, really hard to get things to work. However once your brain realized this was part of the norm it started shifting the mental representation from your conscious thought into your subconscious thought (which is far more effective and powerful) so that reading and algebra became relatively easy. However this takes time because you first have to establish that this mental representation is a new norm *and then* give your body the time to rewire properly. Going back to our pipe organ example we see that there are potentially dozens of individual skills that have to go through this process before we're able to play the pipe organ with any real skill. So take whatever time is required to embed one skill and then multiply it by the number of skills one will need to embed and you've suddenly got a sense of why we aren't all masters of every field out there - layering the skills required to master something takes a hell of a lot of time!

We can actually get a general sense of the order of magnitude involved in *just* the embedding process by looking at a skill that has an extremely well developed learning sequence by this point in history - classical violin performance. Given it's skill that's been around for at least a few hundred years, people have been able to take all the guess work and creative mental representation building that Steve was doing out of it. Therefore learning to

play the violin is really just a process of embed, embed, embed.

Ericsson and two collaborators Ralf Krampe and Clemens Tesch-Romer went to a well known musical academy and selected three groups of violinists - those who were the "best", those who were "better", and those who were "good". They then tried to search for what differentiated these groups from one another. Unsurprisingly, given all we've learned so far, the only predictive component they found was the amount of time people spent practicing - if you practice more you're better at playing the violin. However what's incredible is the sheer amount of time spent practicing. For those in the "best" category, given how much they'd been practicing, it was predicting that by the time they were going to be in their thirties (when folks start really rolling in their careers) they'd have put, on average, somewhere near 25,000 hours of practice in! To put that in perspective, even if you assume they've been practicing since they were 5 years old, that means they've been treating practicing as a part time job (20 hours a week) for their entire life! Embedding skills take a lot of time, energy, and dedication indeed.

This then brings us to Ericsson's conclusion - what leads to skill in any field is simply *deliberate practice*. He,

of course, does a much better job of getting at the specifics (and I'd recommend reading his book *Peak* [10] of which this section is a mere summary) but it more or less comes down to the idea that becoming skilled at something is about two things - (1) not reinventing the wheel, i.e. learning the mental representations that others have already invented in an order that they prescribe and (2) pushing your definition of normal deliberately and consistently in order to truly embed the skills you are learning into your body and brain. However if this is true than it also predicts something that would be rather liberating - that anyone can learn any skill. Note that nowhere in deliberate practice is there any notion of what we might call "talent", all there is is hard work and paying close attention to the coaching others can give you. So is he right, can anyone learn anything? The proof is in the pudding, so let's look at a positively wild example.

Perfect pitch is something that people will often treat more like a sense than a skill. Most assume that you've either got it or you don't. However in 2014 a Japanese psychologist decided to test this assumption. He gathered together a set of children between the ages of 2 and 6 who didn't have perfect pitch, and over the course of several months taught them how to identify 14 chords by just listening to them. For some children it came more

easily than for others, but eventually everyone could identify the 14 chords on their own. Then he tested the kids for perfect pitch. What he found was truly astonishing - every single one of the children had developed perfect pitch and could identify individual notes from sound alone! Something that had always just been considered talent was 100% learn-able!

The conclusion is clear (and if you want more evidence, once again, check out Ericsson's book *Peak* [10]) - anyone can follow in the footsteps of the masters if they're willing to put in the time and use deliberate practice. However this leaves us with a question - what happens when there are no longer any footsteps to follow? What if like Steven Faloan you're finding yourself having to invent the solutions that will bring you to the next level? What about creativity? Clearly if we want to under exceptionalism overall we will need to understand the creative aspect as well. So let's turn to that next.

4.2 Creativity

When we think about creativity we think about novelty - something totally new, a paradigm shift. Strokes of inspiration straight from the well of creative genius. As such,

it can end up feeling kind of haphazard, as if you must just mull over things until that stroke of inspiration occurs. Indeed it can end up feeling as if creativity is something given in droves only to a select few. Reinforcing this sense is the fact that most narratives about creativity are almost always dominated by a select few - cubism by Picasso and Braque, computing by Turing, relativity by Einstein. However, if we take a closer look at the achievements of these creative geniuses, patterns begin to emerge.

As an example, take Picasso. It's often noted that Cubism was inspired by the geometric and abstract nature of traditional African art, especially masks - something that Picasso took a keen interest in [27]. However, Picasso was only able to bring this style into the fold of more mainstream painting because he was one of the most technically proficient painters at the time. In similar fashion Jazz, one of the more influential musical developments in history, arose in New Orleans out of a melding of predominantly white, brass, marching bands and the music and dance traditions of recently emancipated African Americans [32].

On the STEM side there are examples like this as well. Probability and statistics started out as simple accounting for the purposes of playing cards and dice, but has sub-

sequently found applications in pretty much every field in existence. Signals processing is only possible thanks to a kind of mathematics called Fourier Analysis that is more or less the combination of the epicycles that early astronomers used to explain the cosmos and the principles of calculus that Newton developed [34].

Then there's all the inspiration taken from nature. One of the most successful optimization strategies out there - genetic algorithms - came from the flash of insight that if you can create a genome for different solutions you can find the best solution using the same principles backing genetics and macro-evolution in biology. Then there's the fact that down jackets are the result of realizing that some birds don't fly south during the winter, modern windmill fan-blades were inspired by humpback whale fins, and there people are studying ants to figure out how to regulate traffic with autonomous vehicles [26].

All in all, the pattern here should be pretty clear - strokes of insight seem to come from taking the ideas from one field and then finding interesting ways of applying them to another. African masks + european painting becomes Cubism. Tricks from ancient astronomy + calculus becomes Fourier analysis. Bird watching + a need to engineer better clothes becomes down jackets. Creativity is

the art of synthesis - finding useful and/or interesting connections between previously unconnected things.

Now at this point you're probably feeling like this is a gross oversimplification - and you'd be right! For starters, before the insight can happen the tinder for the spark has to be present. There were plenty of artists around in Picasso's day but he was set apart both due to his exceptional technical fluency and his interest in African art. Then there's the fact that the stroke of insight doesn't come of its own accord - clearly there would've been many people aware of genetics, evolution, and the need for better optimizations - yet, in the end, only a handful of people came up with the idea for genetic algorithms. Then there's the process of sorting - many creative people note the fact that for every good idea you have there will be loads of poor ones, and distinguishing one from the other is no trivial matter [18]. Finally, it's a long way from that initial spark to real achievement - Fourier spent a long time formalizing and proving out his ideas before anyone took them seriously, and you can be sure that folks didn't just copy a whale's fin and stick it directly on a windmill turbine. Beyond the initial stroke of insight there are obviously other very important steps involved. Gather, Spark, Sort, Develop in no particular order (because creativity is a messy business) - these are the steps to creating something new.

However, for each of these steps, we can learn from those who've already achieved. We can note that for the cubists and the impressionists (who took key inspiration from Japanese prints [17]) their gathering stage was marked by exploring farther afield than most artists in their day. Einstein is often noted to have spent a lot of time performing thought experiments in his head in order to turn problems this way and thereby facilitate sparks of insight and inspiration. Isaac Asimov (a prolific science fiction author) noted the fact that sometimes it is best to be alone when evaluating and sorting through ideas because many of the initial ideas you'll have will be, in his words, "embarrassing" [18]. But these are just a few examples. In general, there are entire books written on this stuff. From Kaufman and Gregoire's *Wired to Create* [18] to Csikszentmihalyi's *Creativity* [5] there are loads of books out there chock full of lessons learned from studying what sets high achieving creative people apart.

In the light of the last section, all of this should be sounding tremendously familiar. We've got a specific goal - synthesis of previously disparate fields - as well as a whole lot of techniques, advice, and, may I say, mental representations from experts. In other words, while what comes out of the creative process is certainly novel, the process

of being creative is not novel at all! Synthesis is a skill, with experts, that can be mastered itself! It's just a very special skill in the fact that regardless of the field you find yourself in, you're going to want to master this one as well because creativity is how you adapt and push boundaries. But as we've seen in the last section, mastering a skill is no mystery rooted in talent alone - it is instead the result of deliberate practice.

4.3 The Need for Organizations

Alright, at this point we know that the key to exceptional skill and creativity is deliberate practice. However, we also know that deliberate practice for even one skill takes an extraordinary amount of time and, as we just pointed out, one must invest time in practicing creativity too. Remember those violinists who'd spent 20 hours a week for decades to master their craft? That was just for practicing the standardized components. All in all, exceptionalism comes at a very specific cost - and that cost is specialization. Each individual has only so much time and given the massive investment required to master something, there will only be a handful of things you can master in one lifetime.

However, as anyone knows, specialists cannot operate alone. People who operate in sales need things to sell. Musicians need bands or orchestras and places for those bands or orchestras to perform. Mathematicians only really become "useful" when engineers and scientists put their abstractions to use. A doctor is no good without the hospital staff and admin required to keep hospitals running. In short, specialists only become valuable in the coordinated presence of other specialists.

As a result, I, as an individual, will only be able to see benefits from my specialization if this coordination exists. And so we can see that creating high performers through deliberate practice is not enough. While it is definitely a necessary condition for taking full advantage of human potential, it is certainly not sufficient. What you also need are *organizations that can coordinate those specialists*. Put another way, without organizations, specialists are nigh useless. But this also means that organizations that do a poor job developing and/or coordinating those specialists are also useless.

I like the analogy of catalysts here. Within your cell float about loads of proteins, carbohydrates, salts, sugars, and all sorts of other useful, specialized, substances. However, on their own these chemicals just form a weird,

gooey soup because each of these substances on their own don't really do anything. What turns that soup into life are the catalysts that facilitate bringing the various substances together in useful and meaningful ways. This is what transforms a biochemical sludge into one of the most incredible machines in existence - the living cell. Organizations, then, are catalysts for human specialists. Without them there is no way to take full advantage of the human condition and as a consequence no way to tackle and solve our biggest problems or our most daring dreams. And so, if you wish to tackle something huge, if you to achieve in the highest order possible, you must do two things - first you must engender the most exceptional of specialists and then, with equal importance, you must build the organizations that will catalyze them. For without those organizations there will be no mechanism capable of mustering the human skill and energy required to shift a component of our world.

Chapter 5

Systems Engineers

5.1 Diversity First

I've always held that games provide excellent ways of demonstrating and learning real world principles. As an example, take the game Settlers of Catan. The game itself is simple enough, players each gather and trade resources and then use those resources to build up and expand their respective settlements. As they do so they earn victory points and the first person to reach a specific threshold of points wins the game.

In the game resource tiles are not evenly distributed

among the players and who needs what depends on what each player is trying to achieve. As a result of this it doesn't take long before different players end up with disproportionately large stockpiles of certain resources and an absolute dearth of others. This sets things up for possibly one of the most entertaining components of the game - trade. An arena of backstabbing, failed loans, and bribes all trade in the game is based around one thing - differentials in value between different players. For example suppose I happen to have a large surplus of sheep but am in desperate need of stone to build cities. I will end up looking for players who are in the opposite position - having more stone than they really want or need but are in need of sheep. This differential in value sets us up for what is known in game theory as a positive sum game - by cooperating we will both end up with more value than either of us started out with. And if the deal is good enough others might actually look to interrupt our bargain in order to limit our perceived advantage.

This simple example demonstrates a very broad and far reaching principle that has driven quite a lot of human development - differentials in what people value creates the opportunity for positive sum games and positive sum games generate growth. Loads of other examples of this principle abound throughout history. The rush to colo-

nize the New World came from sudden access to things Europeans valued a great deal like fancy furs and silver for coinage that the New World had relatively easy access to (unfortunately no one ever thought to cooperate with the Native Americans but that is a diatribe for another essay). In the wake of global trade and global industrialization each city in the world has been able to become hyper-specialized in producing specific kinds of things allowing for loads of positive sum games that have driven a lot of the progress we've seen in the past half a century [39]. Then looking at specialized industries like health care we see this kind of pattern creating a diversification of jobs. Increasingly specialized doctors need increasingly specialized nurses, administrative staff, tools, and facilities.

In general the loop is clear. As people specialize they generate both specialized kinds of value but also specialized kinds of needs. If these needs and values get matched with other different but compatible specialists through positive sum games, the sum total value ends up larger than its parts. These additional resources (whether they be in the form of knowledge, capability, time, money, etc) can then be used to drive additional specialization to drive even more powerful positive sum games, and so on.

In sum, specialists open the opportunity for positive

sum games and positive sum games open the opportunity for specialists - a powerful feedback loop that doesn't just redistribute the pie through even trades (zero sum games) but actually results in growth.

This, however, points out something really interesting about the nature of work and growth. In my own experience I have oftentimes (if not almost always) seen the focus surrounding achievements go not to the *teams* but to the *stars*. Sports focuses on the star players, music focuses on the star performers, engineering focuses on the folks "at the cutting edge". Obviously high performers are important but positive sum games work because of *differentials in capabilities and value*. What matters is pulling together groups or teams that collaborate in the most powerful of ways across a variety of different skill sets. A team of highly compatible, highly differential players is always going to beat a team of high performers that either don't get along or are too close to one another in capabilities. A team of quarterbacks or strikers wouldn't get very far against a relatively mediocre but well diversified team.

High performance only matters in the presence of the diversification required to take advantage of it.

5.2 Process not Product

Alright so we know positive sum games help us generate growth but we've got one problem - single positive sum games don't get us anywhere and are usually pretty hard to setup. Calling back to our game of Settlers of Catan a single trade is not going to win the game for me - I need to make repeated good trades in order to actually grow my settlements. And each trade I make has to be thought through, bargained for, and sealed. That's a lot of overhead.

In general this applies to the real world as well. Single sales don't make companies, continued, predictable sales do. So should we renegotiate every single deal, every single time? Rarely. In general it makes sense to save on the overhead as much as possible and instead of thinking about single actions, think about creating resilient processes that will continue to produce positive sum interactions for us. As Meadows points out repeatedly in her book *Thinking in Systems* [21] single interactions don't lead to long term reliable patterns of behavior, only systems do so. So rather than spending loads of time hand crafting each and every interaction it makes a lot more sense to put that time and energy into building a *process* that will reliably produce the results we want. Put another way - process over prod-

uct.

5.3 Avoiding the Chaos

Now what we've talked about so far are pretty limited, small scale interactions - positive sum processes between very specific parties. However usually meeting larger goals takes the coordination of several different positive sum processes. As an example let's take an example out of Meadows's systems zoo - a car dealer [21]. In this situation the car dealer has not one but two positive sum games to play - one with the customers and one with the car manufacturers. However, while this situation seems only trivially more complicated, it quickly illustrates what can go wrong with more complex systems. What's important in this example is that the car dealer is having to balance out how quickly she buys cars from the manufacturer with how quickly she sells them.

Now in this example, as with the real world, there are delays involved. It takes time to place the orders to the car manufacturer and it takes time to get a good sense of how customer behavior has changed. As Meadows demonstrates, these kinds of delays result in oscillations in the stock of cars at the dealership at anytime. Basically, what

happens is that if sales increases slightly, given it takes time to notice the shift a drop in inventory will result. This drop in inventory ends up pushing the car dealer to put in a large order to the manufacturer. However because this order needs to compensate not only for the loss in inventory but also the increased rate of sales at some point the inventory overshoots the sales alone. But it takes time to correct this with the manufacturer and by that point the dealer will be trying to correct downward to deal with the excess of stock. This then brings us back to a lack of stock and the cycle continues.

This however is where things get interesting. The obvious thing to do here is to remove the delays as they seem to be the source of the problem. However there is really only one delay the car dealer has any control over - her own response time to customer sales. But as Meadows demonstrates by actually simulating what happens with a shorted delay, the oscillations only get worse! More or less the quicker response also results in more dramatic and therefore over-compensatory responses. As it turns out the way to dampen the oscillations is not to reduce the perception delay but to increase it so that it better matches the delay from the car manufacturer.

This demonstrates a simple but profound principle il-

lustrated throughout Meadows' book - rational actors in complex systems do not produce rational results if they only think about their individual interactions with the system. What's required to get the system to work properly is to look at the system as a whole and tune the various interactions to work well *with one another*. And sometimes the required changes seem to make little sense within the specific components that need to make the change. Our dealer was having issues due to delays but it turned out that the solution was actually making one of the delays longer!

Our car dealership was a toy example but real examples of these principles abound. Politicians in democratic governments are reelected every few years. This makes good sense if you're trying to provide a quick feedback for your voters. However it also leads to politics that has a hard time dealing with long term issues as politicians are motivated by their immediate next upcoming election. Given the risk involved in lending money it only makes sense to receive some kind of return on investment. Yet this results in a self reinforcing feedback loop that inexorably drives money into fewer and fewer hands. The principle is clear - people can act totally rationally with respect to the issue at hand and yet drive a system to horrendous results.

What this means is quite simple - systems require system engineers. It is not enough to simply throw together a system and hope that everyone doing their part will get you the intended results. You need folks who will monitor the system as a whole and modify and improve it as needed to meet the *actual* aim of the system. Furthermore it is up to these systems engineers to notice when components of the system have grown old and need to be retired or when new components are required to meet or grow the system.

The people currently in those kinds of positions go by the title - manager. However, (at least in my experience) this is a relatively radical way of looking at a manager's role. Most of the time when thinking about management it seems that people tend to think of a manager like a general during a battle - handing out orders, monitoring progress toward goals, potential risks, etc. In the moment, this kind of work is obviously important, however to our earlier point about single trades not creating a business, single battles don't win a war. And this is where systems thinking comes in. Battles are fought by armies, but wars are fought by militaries. Militaries are composed of all the processes for recruitment, training, promoting, gathering intelligence, selecting engagements, developing new technologies, etc. Battles are just individual expressions of these systems. So if a military wants to stand a chance

of winning battles consistently they'd better not just focus on the tactics of individual battles but also work on developing the systems that drive their military. In a similar way, while managers are certainly responsible for the tactics around driving specific deliverables, they should really see those tactics as expressions of the system for which they are ultimately responsible.

Managers should be systems engineers first and tacticians second. Indeed one might even go so far as to say that any time they have to intervene they've found a flaw in their system that needs to be addressed.

5.4 Recursion through Hierarchy

The example of a military is a good one because it also illustrates a pretty general problem in systems engineering - how to deal with scale. One cannot expect a single person to manage every single subsystem inside of something so large as a country's military - there's simply not enough time to do so. In general we'd expect this kind of problem to arise in pretty much every successful system. Why? Because remember the whole point of positive sum games is to generate growth. That means positive sum systems grow too and so, if they're successful, at some point scale

is going to become an issue.

Thankfully we can take a queue from our own biology. To understand your anatomy you don't necessarily need to dive all the way down to biochemistry - understanding the general anatomical systems will do. If you want to understand those better you need only learn about the organs that compose them. Organs in turn are composed of tissues, which are composed of cells, which are composed of organelles, which are, finally, composed of biochemistry. Your body is an exquisite example of hierarchy. At each new level of complexity all of the components have clearly defined interfaces and roles which allows them to be considered, more or less, as black boxes - you don't have to understand their internal systems to understand how they work relative to the system they're a part of.

Hierarchies are how systems end up dealing with scale. In general once a system becomes overwhelmingly complicated it must find ways to divide its components into individual, independent subsystems into which all of the underlying complexity can be packed and then hidden. The resulting system will then be back to a manageable level of complexity allowing for further growth of the system.

As such, hierarchies require three things - (1) clear,

distinct roles for each component, (2) clear interfaces between those components, and (3) systems engineers who can manage and be responsible for the internals of each subsystem. Without these conditions the hierarchy either doesn't effectively resolve the complexity or results in the eventual degradation of the internal subsystems. But with these, hierarchies can be applied recursively to allow systems to scale, at least in theory, indefinitely.

5.5 Pulling it All Together

Okay so we've noted how positive sum games enable you to use specialists to drive growth, how thinking in terms of systems allows you to turn that growth from an effect and into a pattern, how systems engineers are required to get systems to actually reach their goals, and how the scale that eventually comes from the growth of those systems can be handled by building hierarchies. This provides us a useful map for thinking about how to get the most out of our specialists, drive them towards meeting useful goals, and, in the long run grow the capabilities and value available to us. But of all of this points out something very simple and very profound - *organizational development is positive sum systems engineering*.

Why does this matter? If you listen to how our world talks about the "big" issues you'll see the same thing over and over again - here's the solution that will save us. If we just build carbon sequestration technologies we'll solve climate change. If we can just elect the right leaders we'll remove poverty. Let's all get together and clean up the local lake so we don't have to deal with pollution anymore. Now don't get me wrong, all of these things would be great! However none of these solutions address the fact of the matter that the systems that got us into these messes into the first place will still be there. It may seem like the lack of a solution means nothing's there but *systems always exist and the current behavior (or lack thereof) is a result of them*.

Furthermore as we saw a few sections ago, adding helpful technology can just create even more devastation. For example, our creating better and better fishing vessels has actually resulted in fewer and fewer fish [21] because we haven't addressed the underlying lack of sustainability in the underlying system!

As a result, rather than trying to pull together specialists to create the next grand new technology or power the next great intervention, we should instead be trying to engineer the kinds of systems that wouldn't drive us toward

these problems in the first place. Indeed if we build the right systems, we will end up empowering the underlying specialists to self evolve the needed solutions. However if we focus only on the solution and leave the old system in place that same system will eventually just erode our efforts away. Organization development is not about creating solutions, its about engineering effective systems.
